(54) Title: FIREWALL SECURITY PROTECTION OF PARALLEL PROCESSING IN A GLOBAL COMPUTER NETWORKING ENVIRONMENT

(57) Abstract

This invention generally relates to one or more computer networks having personal computers or network servers with master (30) and slave microprocessors (40) and a firewall (50) between them. The microprocessors linked by broadband transmission means and having hardware, software, firmware, and other means such that at least one parallel processing operation occurs that involve at least two computers in the network. More particularly, this invention relates to one or more large networks composed of smaller networks and large number of computers connected, like the Internet, wherein more than one separate parallel processing operation involving more than one different set of computers occurs simultaneously and wherein ongoing processing linkages can be established between virtually any microprocessors of separate computers connected to the network. Still more particularly, this invention relates to business enabling the shared use of network microprocessor for parallel and other processing.

Firewall Security Protection of Parallel Processing in a Global Computer Networking Environment

BACKGROUND OF THE INVENTION

This invention generally relates to one or more computer networks having computers like personal computers
5 or network computers such as servers with microprocessors preferably linked by broadband transmission means and having hardware, software, firmware, and other means such that at least two parallel processing operations occur that involve at least two sets of computers in the network or in
10 networks connected together, a form of metacomputing. More particularly, this invention relates to one or more large networks composed of smaller networks and large numbers of computers connected, like the Internet, wherein more than one separate parallel or massively parallel processing
15 operation involving more than one different set of computers occurs simultaneously. Even more particularly, this invention relates to one or more such networks wherein more than one (or a very large number of) parallel or massively parallel microprocessing processing operations
20 occur separately or in an interrelated fashion; and wherein ongoing network processing linkages can be established between virtually any microprocessors of separate computers connected to the network.

Still more particularly, this invention relates
25 generally to a network structure or architecture that enables the shared used of network microprocessors for parallel processing, including massive parallel processing, and other shared processing such as multitasking, wherein personal computer owners provide microprocessor processing
30 power to a network, preferably for parallel or massively parallel processing or multitasking, in exchange for network linkage to other personal and other computers

supplied by network providers such as Internet Service Providers (ISP's), including linkage to other microprocessors for parallel or other processing such as multitasking. The financial basis of the shared use
5 between owners and providers being be whatever terms to which the parties agree, subject to governing laws, regulations, or rules, including payment from either party to the other based on periodic measurement of net use or provision of processing power or preferably involving no
10 payment, with the network system (software, hardware, etc) providing an essentially equivalent usage of computing resources by both users and providers (since any network computer operated by either entity can potentially be both a user and provider of computing resources alternately (or
15 even simultaneously, assuming multitasking), with potentially an override option by a user (exercised on the basis, for example, of user profile or user's credit line or through relatively instant payment).

Finally, this invention relates to a network system
20 architecture including hardware and software that provides use of the Internet or its future equivalents or successors (and most other networks) without cost to most users of personal computers or most other computers, while also providing those users (and all other users, including of
25 supercomputers) with computer processing performance that can at least double every 18 months through metacomputing means. This metacomputing performance increase provided by the new MetaInternet (or Metanet for short) is in addition to all other performance increases, such as those already
30 anticipated by Moore's Law.

By way of background, the computer industry has been governed over the last 30 years by Moore's Law, which holds that the circuitry of computer chips has been shrunk substantially each year, yielding a new generation of chips

every 18 months with twice as many transistors, so that microprocessor computing power is effectively doubled every year and a half.

The long term trend in computer chip miniaturization is projected to continue unabated over the next few decades. For example, slightly more than a decade ago a 16 kilobit DRAM memory chip (storing 16,000 data bits) was typical; the standard in 1996 was the 16 megabit chip (16,000,000 data bits), which was introduced in 1993; and industry projections are for 16 gigabit memory chips (16,000,000,000 data bits) to be introduced in 2008 and 64 gigabit chips in 2011, with 16 terabit chips (16,000,000,000,000 data bits) conceivable by the mid-to-late 2020's. This is a thousand-fold increase regularly every fifteen years. Hard drive speed and capacity are also growing at a spectacular rate.

Similarly regular and enormous improvements are anticipated to continue in microprocessor computing speeds, whether measured in simple clock speed or MIPS (millions of instructions for second) or numbers of transistors per chip. For example, performance has improved by four or five times every three years since Intel launched its X86 family of microprocessors used in the currently dominant "Wintel" standard personal computers. The initial Intel Pentium Pro microprocessor was introduced in 1995 and is a thousand times faster than the first IBM standard PC microprocessor, the Intel 8088, which was introduced in 1979. By 1996 the fastest of microprocessors, like Digital Equipment Corp.'s Alpha chip, is faster than the processor in the original Cray Y-MP supercomputer.

Both microprocessors and software (and firmware and other components) are also evolving from 8 bit and 16 bit systems into 32 bit systems that are becoming the standard today, with some 64 bit systems like the DEC Alpha already

introduced and more coming, with future increases to 128 bit also likely.

A second major development trend in the past decade or so has been the rise of parallel processing, a computer architecture utilizing more than one CPU microprocessor (often many more, even thousands of relatively simple microprocessors, for massively parallel processing) linked together into a single computer with new operating systems having modifications that allow such an approach. The field of supercomputing has been taken over by this approach, including designs utilizing many identical standard personal computer microprocessors.

Hardware, firmware, software and other components specific to parallel processing are in a relatively early stage of development compared to that for single processor computing, and therefore much further design and development is expected in the future to better maximize the computing capacity made possible by parallel processing. One likely improvement is much more effective system architecture for parallel processing that does not rely on the multiple microprocessors having to share memory, thereby allowing more independent operation of those microprocessors, each with their own discrete memory, like current personal computers, workstations and most other computer systems architecture; for unconstrained operation, each individual microprocessor must have rapid access to sufficient memory.

Several models of personal computers are now available with more than one microprocessor. It seems inevitable that in the future personal computers, broadly defined to include versions not currently in use, will also employ parallel computing utilizing multiple microprocessors or massively parallel computing with very large numbers of microprocessors. Future designs, such Intel's Merced chip,

are expected to have a significant number of parallel processors on a single microprocessor chip.

A form of parallel processing is also being employed within microprocessor design itself. The generation in 5 1996 of microprocessors such as the Intel Pentium have more than one data path within the microprocessor in which data can be processed, with two to three paths being typical.

The third major development trend is the increasing size of bandwidth, which is a measure of communications 10 power between computers connected by a network. Before now, the local area networks and telephone lines typically linking computers including personal computers have operated at speeds much lower than the processing speeds of a personal computer. For example, a typical Intel Pentium 15 operates at 100 MIPS (millions of instructions per second), whereas a typical Ethernet connecting the PC's is 100 times slower at 10 megabits per second (Mbps) and telephone lines are very much slower, the highest typical speed now being about 28.8 kilobits per second.

Now, however, the situation is expected to change 20 dramatically, with bandwidth being anticipated to expand from 5 to 100 times as fast as the rise of microprocessor speeds, due to the use of coaxial cable, wireless, and fiber optic cable. Telecommunication providers are now 25 making available fiber connections supporting bandwidth of 40 gigabits per second.

Technical improvements are expected in the near term which will make it possible to carry over 2 gigahertz (billions of cycles per second) on each of 700 wavelength 30 stream, adding up to more than 1,700 gigahertz on every single fiber thread. Experts believe that the bandwidth of optical fiber has been utilized one million times less fully than the bandwidth of coaxial or twisted pair copper lines. Within a decade, 10,000 wavelength streams per

fiber are expected and 20 wavelengths on a single fiber is already commercially available.

Other network connection developments such as asynchronous transfer mode (ATM) and digital signal processors, which are improving their price/performance tenfold every two years, are also supporting the rapid increase in bandwidth. The increase in bandwidth reduces the need for switching and switching speed will be greatly enhanced when practical optical switches are introduced in the fairly near future, potentially reducing costs substantially.

The result of this huge bandwidth increase will be extraordinary: within just a few years when sufficient network infrastructure is in place, it will be technically possible to connect virtually any computer to a network at a speed that equals or exceeds the computer's own internal bus speed, even as that bus speed itself is increasing significantly. The bus of a computer is its internal network connecting its components such as microprocessor, random access memory (RAM), hard-drive, modem, floppy drive, and CD-ROM; for recent personal computers it has been only about 40 megabits per second, but is now up to a gigabit per second on Intel's Pentium PCI bus.

Despite these tremendous improvements anticipated in the future, the unfortunate present reality is that a typical personal computer (PC) is already so fast that its microprocessor is essentially idle during most of the time the PC is in actual use and that operating time itself is but a small fraction of those days the PC is even in any use at all. The reality is that nearly all PC's are essentially idle during roughly all of their useful life. A realistic estimate is that its microprocessor is in an idle state 99.9% of the time (disregarding current unnecessary microprocessor busywork like executing screen

saver programs, which have been made essentially obsolete by power-saving CRT monitor technology, which is now standard in the PC industry).

Given the fact that the reliability of PC's is so
5 exceptionally high now, with the mean time to failure of all components typically several hundred thousand hours or more, the huge idle time of PC's represents a total loss; given the high capital and operating costs of PC's, the economic loss is very high. PC idle time does not in
10 effect store a PC, saving it for future use, since the principle limiting factor to continued use of today's PC's is obsolescence, not equipment failure from use.

Moreover, there is growing concern that Moore's Law, which as noted above holds that the constant
15 miniaturization of circuits results in a doubling of computing power every 18 months, cannot continue to hold true much longer. Indeed, Moore's Law may now be nearing its limits for silicon-based devices, perhaps by as early as 2004, and no new technologies have yet emerged that
20 currently seem with reasonable certainty to have the potential for development to a practical level by then.

SUMMARY OF THE INVENTION

However, the confluence of all three of the established major trends summarized above -- supercomputer-
25 like personal computers, the spread of parallel processing using personal computer microprocessors (particularly massively parallel processing), and the enormous increase in network communications bandwidth -- have made possible in the near future a surprising solution to the hugely
30 excessive idleness problem of personal computers (and to the problematic possible end of Moore's Law), with very high potential economic savings.

The solution is use those mostly idle PC's (or their equivalents or successors) to build a parallel or massively parallel processing computer utilizing a very large network like the Internet or, more specifically, like the World Wide Web (WWW), or their equivalents or eventual successors like the MetaInternet (and including Internet II, which is under development now and which will utilize much broader bandwidth and will coexist with the Internet, the structure of which is in ever constant hardware and software upgrade) with broad bandwidth connections. The prime characteristic of the Internet is of course the very large number of computers of all sorts already linked to it, with the future potential for effectively universal connection; it is a network of networks of computers that provides nearly unrestricted access (other than cost) worldwide. The rapidly growing infrastructure of very broad bandwidth of network communications can be used to link personal computers externally in a manner equivalent to the internal buses of the personal computers, so that no processing constraint is be imposed on linked personal computers by data input or output, or throughput; the speed of the microprocessor itself can be the only processing constraint of the system.

This makes external parallel processing possible, including massively parallel processing, in a manner paralleling more conventional internal parallel processing.

Optimally, the World Wide Web (or its equivalents or successors) can be transformed into a huge virtual massively parallel processing computer or computers, with potential through its established hyperlinks connections to operate in a manner at least somewhat like a neural network or neural networks, since the speed of transmission in the broadband linkages is so great that any linkage between two microprocessors is virtually equivalent to direct,

physically close connections between those microprocessors.

With further development, digital signal processor-type microprocessors or even analogue microprocessors may be optimal for this approach. Networks with WWW-type
5 hyperlinks incorporating digital signal processor-type microprocessor (or successors or equivalents) could operate separately from networks of conventional microprocessors (or successors or equivalents) or with one or more connections between such differing networks or with
10 relatively complete integration between such differing networks. Simultaneous operation across the same network connection structure should be possible.

Such broad bandwidth networks of computers enable every PC to be fully utilized or nearly so. Because of the
15 extraordinary extent to which existing PC's are currently idle, at optimal performance this new system can potentially result in a thousand-fold increase in computer power available to each and every PC user (and any other user); and, on demand, almost any desired level of
20 increased power, limited mostly by the increased cost, which however is relatively far less than possible from any other conceivable computer network configuration. This revolutionary increase is on top of the extremely rapid, but evolutionary increases already occurring in the
25 computer/network industry discussed above.

The metacomputing hardware and software means of the MetaInternet provides performance increases that can likely at least double every eighteen months based on the doubling of personal computers shared in a typical parallel
30 processing operation by a standard PC user, starting first with at least 2 PC's, then about 4, about 8, about 16, about 32, about 64, about 128, about 256, and about 512, for example. After about fifteen years, for example, it is anticipated that each standard PC user will likely be able

to use about 1024 personal computers for parallel processing or any other shared computing use, while generally using the Internet or its successors like the MetaInternet for free. At the other end of the performance spectrum, supercomputers can experience a similar performance increase generally, but ultimately the performance increase is limited primarily by cost of adding temporary network linkages to available PC's, so there is definite potential for a quantum leap in supercomputer performance.

Network computer systems as described above offer almost limitless flexibility due to the abundant supply of heretofore idle connected microprocessors. This advantage allows "tightly coupled" computing problems (which normally are difficult to process in parallel) to be solved without knowing in advance (as is now necessary in relatively massively parallel processing) how many processors are available, what they are and their connection characteristics. A minimum number of equivalent processors (with equivalent other specs) can be easily found nearby in a massive network like the Internet and assigned within the network from those multitudes available nearby. Moreover, the number of microprocessors used can be almost completely flexible, depending on the complexity of the problem, and limited only by cost. The current problem of time delay can be solved largely by the widespread introduction of broad bandwidth connections between computers processing in parallel.

BRIEF DESCRIPTION OF THE DRAWINGS

Figure 1 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a meter means which measures flow of

computing during a shared operation such as parallel processing between a typical PC user and a network provider.

Figure 2 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of another meter means which measures the flow of network resources, including shared processing, being provided to a typical PC user and a network provider.

Figure 3 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of another meter means which, prior to execution, estimates the level of network resources, and their cost, of a shared processing operation requested by a typical PC user from a network provider.

Figure 4A-4C are simplified diagrams of a section of a computer network, such as the Internet, showing in a sequence of steps an embodiment of a selection means whereby a shared processing request by a PC is matched with a standard preset number of other PC's to execute shared operation.

Figure 5 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a control means whereby the PC, when idled by its user, is made available to the network for shared processing operations.

Figure 6 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a signal means whereby the PC, when idled by its user, signals its availability to the network for shared processing operations.

Figure 7 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a receiver and/or interrogator means whereby the network receives and/or queries the availability for

shared processing status of a PC within the network.

Figure 8 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a selection and/or utilization means whereby the network locates available PC's in the network that are located closest to each other for shared processing.

Figure 9 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a system architecture for conducting a request initiated by a PC for a search using parallel processing means that utilizes a number of networked PC's.

Figures 10A-10I are simplified diagrams of a section of a computer network, such as the Internet, showing an embodiment of a system architecture utilizing a firewall to separate that part of a networked PC (including a system reduced in size to a microchip) that is accessible to the network for shared processing from a part that is kept accessible only to the PC user; also showing the alternating role that preferably each PC in the network can play as either a master or slave in a shared processing operation involving one or more slave PC's in the network; and showing a home or business network system, which can be configured as an Intranet; in addition, showing PC and PC microchips controlled by a controller (including remote) with limited or no processing capability; and showing PC and PC microchips in which a firewall is can be reconfigured by a PC user.

Figure 11 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a system architecture for connecting clusters of PC's to each other by wireless means, to create the closest possible (and therefore fastest) connections.

Figure 12 is a simplified diagram of a section of a computer network, such as the Internet, showing an

embodiment of a system architecture for connecting PC's to a satellite by wireless means.

Figure 13 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a system architecture providing a cluster of networked PC's with complete interconnectivity by wireless means.

Figure 14A is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a transponder means whereby a PC can identify one or more of the closest available PC's in a network cluster to designate for shared processing by wireless means. Figure 14B shows clusters connected wirelessly; Figure 14C shows a wireless cluster with transponders and with a network wired connection to Internet; Figure 14D shows a network client/server wired system with transponders.

Figure 15 is a simplified diagram of a section of a computer network, such as the Internet, showing an embodiment of a routing means whereby a PC request for shared processing can be routed within a network using preferably broad bandwidth connection means to another area in a network with one or more idle PC's available.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The new network computer utilizes PC's as providers of computing power to the network, not just users of network services. These connections between network and personal computer are enabled by a new form of computer/network financial structure that is rooted on the fact that economic resources being provided the network by PC owners (or leaser) are similar in value to those being provided by the network provider providing connectivity.

Unlike existing one way functional relationships between network providers such as internet service providers (often currently utilizing telecommunications networks for connectivity) and PC users, wherein the network provider provides access to a network like the internet for a fee (much like cable TV services), this new relationship recognizes that the PC user is also providing the network access to the user's PC for parallel computing use, which has a similar value. The PC thus both provides and uses services on the network, alternatively or potentially even virtually simultaneously, in a multitasking mode.

This new network operates with a structural relationship that is roughly like that which presently exists between an electrical power utility and a small independent power generator connected to the utility, wherein electrical power can flow in either direction depending on the operating decisions of both parties and at any particular point in time each party is in either a debt or credit position relative to the other based on the net direction of that flow for a given period, and is billed accordingly. In the increasingly deregulated electrical power industry, electrical power (both its creation and transmission) is becoming a commodity bought and sold in a competitive marketplace that crosses traditional borders. With the structural relationship proposed here for the new network, parallel free market structures can develop over time in a new computer power industry dominated by networks of personal computers in all their forms providing shared processing.

For this new network and its structural relationships, a network provider is defined in the broadest possible way as any entity (corporation or other business, government, not-for-profit, cooperative, consortium, committee,

association, community, or other organization or individual) that provides personal computer users (very broadly defined below) with initial and continuing connection hardware and/or software and/or firmware and/or other components and/or services to any network, such as the Internet and Internet II or WWW or their present or future equivalents, coexistors or successors, like the MetaInternet, including any of the current types of Internet access providers (ISP's) including telecommunication companies, television cable or broadcast companies, electrical power companies, satellite communications companies, or their present or future equivalents, coexistors or successors. The connection means used in the networks of the network providers, including between personal computers or equivalents or successors, is preferably very broad bandwidth, by such means as fiber optic cable or wireless for example, but not excluding any other means, including television coaxial cable and telephone twisted pair, as well as associated gateways, bridges, routers, and switches with all associated hardware and/or software and/or firmware and/or other components and their present or future equivalents or successors. The computers used by the providers include any computers, including mainframes, minicomputers, servers, and personal computers, and associated their associated hardware and/or software and/or firmware and/or other components, and their present or future equivalents or successors.

Other levels of network control beyond the network provider can also exist to control any aspect of the network structure and function, any one of which levels may or may not control and interact directly with the PC user.

For example, at least one level of network control like the World Wide Web Consortium (W3C) or Internet Society

(ISOC) or other ad hoc industry consortia can establish and ensure compliance with any prescribed network standards and/or protocols and/or industry standard agreements for any hardware and/or software and/or firmware and/or other
5 component connected to the network. Under the consensus control of these consortia/societies, other levels of network control can deal with administration and operation of the network. These other levels of network control can potentially be constituted by any network entity, including
10 those defined immediately above for network providers.

The principal defining characteristic of the network herein described being communication connections (including hardware and/or software and/or firmware and/or other component) of any form, including electromagnetic (such as
15 light and radio or microwaves) and electrochemical (and not excluding biochemical or biological), between PC users, optimally connecting (either directly or indirectly) the largest number of users possible, like the Internet (and Internet II) and WWW and equivalents and successors, like
20 the MetaInternet. Multiple levels of such networks can coexist with different technical capabilities, like Internet and Internet II, but would certainly have interconnection and therefore would certainly communicate freely between levels, for such standard network functions
25 as electronic mail, for example.

And a personal computer (PC) user is defined in the broadest possible way as any individual or other entity using a personal computer, which is defined as any computer, digital or analog or neural, particularly
30 including microprocessor-based personal computers having one or more microprocessors (each including one or more parallel processors) in their general current form (hardware and/or software and/or firmware and/or any other component) and their present and future equivalents or

successors, such as workstations, network computers, handheld personal digital assistants, personal communicators such as telephones and pagers, wearable computers, digital signal processors, neural-based
5 computers (including PC's), entertainment devices such as televisions, video tape recorders, videocams, compact or digital video disk (CD or DVD) player/recorders, radios and cameras, other household electronic devices, business
10 electronic devices such as printers, copiers, fax machines, automobile or other transportation equipment devices, and other current or successor devices incorporating one or more microprocessors (or functional or structural
equivalents), especially those used directly by individuals, utilizing one or more microprocessors, made of
15 inorganic compounds such as silicon and/or other inorganic or organic compounds; current and future forms of mainframe computers, minicomputers, microcomputers, and even supercomputers are also be included. Such personal
computers as defined above have owners or leasers, which
20 may or may not be the same as the computer users. Continuous connection of computers to the network, such as the Internet, WWW, or equivalents or successors, is preferred, but clearly not required, since connection can
also be made at the initiation of a shared processing
25 operation.

Parallel processing is defined as one form of shared processing involving two or more microprocessors used in solving the same computational problem or other task. Massively parallel microprocessor processing involves large
30 numbers of microprocessors. In today's technology, massive parallel processing can probably be considered to be about 64 microprocessors (referred to in this context as nodes) and over 7,000 nodes have been successfully tested in an Intel supercomputer design using PC microprocessors

(Pentium Pros). It is anticipated that continued software improvements will make possible effective use of a much larger number of nodes, very possibly limited only by the number of microprocessors available for use on a given network, even an extraordinarily large one like the Internet or its equivalents and/or successors, like the MetaInternet.

Broadband wavelength or broad bandwidth network transmission is defined here to mean a transmission speed (usually measured in bits per second) that is at least high enough (or roughly at least equivalent to the internal clock speed of the microprocessor or microprocessors times the number of microprocessor channels equaling instructions per second or operations per second or calculations per second) so that the processing input and output of the microprocessor is substantially unrestricted, particularly including at peak processing levels, by the bandwidth of the network connections between microprocessors that are performing some form of parallel processing, particularly including massive parallel processing. Since this definition is dependent on microprocessor speed, it increases as microprocessor speeds increase. A rough example might be a 1996 era 100 MIPS (millions instructions per second) microprocessor, for which a broad bandwidth connection is greater than 100 megabits per second (Mbps); this is a rough approximation. However, a preferred connection means referenced above is fiber optic cable, which in 1996 already provided multiple gigabit bandwidth on single fiber thread and will improve significantly in the future, so the use of fiber optic cable virtually assures broad bandwidth for data transmission that is far greater than microprocessor speed to provide data to be transmitted. The connection means to provide broad bandwidth transmission can be either wired or wireless,

with wireless generally preferred for mobile personal computers (or equivalents or successors) and as otherwise indicated below. Wireless connection bandwidth is also increasing rapidly and can be considered to offer
5 essentially the same benefit as fiber optic cable: data transmission speed that far exceeds data processing speed.

The financial basis of the shared use between owners/ lessors and providers is whatever terms to which the parties agree, subject to governing laws, regulations, or
10 rules, including payment from either party to the other based on periodic measurement of net use or provision of processing power.

In one embodiment, as shown in Figure 1, in order for this network structure to function effectively, there is a
15 meter device 5 (comprised of hardware and/or software and/or firmware and/or other component) to measure the flow of computing power between PC 1 user and network 2 provider, which might provide connection to the Internet and/or World Wide Web and/or Internet II and/or any present
20 or future equivalent or successor 3, like the MetaInternet.

In one embodiment, the PC user should be measured by some net rating of the processing power being made available to the network, such as net score on one or more standard tests measuring speed or other performance characteristics
25 of the overall system speed, such as PC Magazine's benchmark test program, ZD Winstone (potentially including hardware and/or software and/or firmware and/or other component testing) or specific individual scores for particularly important components like the microprocessor
30 (such as MIPS or millions of instructions per second) that may be of application-specific importance, and by the elapsed time such resources were used by the network. In the simplest case, for example, such a meter need measure only the time the PC was made available to the network for

processing 4, which can be used to compare with time the PC used the network (which is already normally measured by the provider, as discussed below) to arrive at a net cost; potential locations of such a meter include at a network computer such as a server, at the PC, and at some point on the connection between the two. Throughput of data in any standard terms is another potential measure.

In another embodiment, as shown in Figure 2, there also is a meter device 7 (comprised of hardware and/or software and/or firmware and/or other component) that measures the amount of network resources 6 that are being used by each individual PC 1 user and their associated cost. This includes, for example, time spent doing conventional downloading of data from sites in the network or broadcast from the network 6. Such metering devices currently exist to support billing by the hour of service or type of service is common in the public industry, by providers such as America Online, Compuserve, and Prodigy.

The capability of such existing devices is enhanced to include a measure of parallel processing resources that are allocated by the Internet Service Provider or equivalent to an individual PC user from other PC users 6, also measuring simply in time. The net difference in time 4 between the results of meter 5 and meter 7 for a given period provides a reasonable billing basis.

Alternately, as shown in Figure 3, a meter 10 also estimates to the individual PC user prospectively the amount of network resources needed to fulfill a processing request from the PC user to the network (provider or other level of network control) and associated projected cost, provide a means of approving the estimate by executing the request, and a realtime readout of the cost as it occurs (alternatively, this meter might be done only to alert 9 the PC user that a given processing request 8 falls outside

normal, previously accepted parameters, such as level of cost). To take the example of an unusually deep search request, a priority or time limit and depth of search should optimally be criteria or limiting parameters that the user can determine or set with the device.

Preferably, the network involves no payment between users and providers, with the network system (software, hardware, etc) providing an essentially equivalent usage of computing resources by both users and providers (since any network computer operated by either entity can potentially be both a user and provider of computing resources (even simultaneously, assuming multitasking), with potentially an override option by a user (exercised on the basis, for example, of user profile or user's credit line or through relatively instant payment).

Preferably, as shown in Figures 4A-4C, the priority and extent of use of PC and other users can be controlled on a default-to-standard-of-class-usage basis by the network (provider or other) and overridden by the user decision on a basis prescribed by the specific network provider (or by another level of network control). One obvious default basis is to expend up to a PC's or other user's total credit balance with the provider described above and the network provider then to provide further prescribed service on an debt basis up to some set limit for the user; different users might have different limits based on resources and/or credit history.

A specific category of PC user based, for example, on specific microprocessor hardware owned or leased, might have access to a set maximum number of parallel PC's or microprocessors, with smaller or basic users generally having less access and vice versa. Specific categories of users might also have different priorities for the execution of their processing by the network. A very wide

range of specific structural forms between user and provider are possible, both conventional and new, based on unique features of the new network computer system of shared processing resources.

5 For example, in the simplest case, in an initial system embodiment, as shown in Fig. 4A, a standard PC 1 user request 11 for a use involving parallel processing might be defaulted by system software 13, as shown in Fig. 4B, to the use of only one other essentially identical PC 1:
10 microprocessor for parallel processing or multitasking, as shown in Figure 4C; larger standard numbers of PC microprocessors, such as about three PC's at the next level, as shown in later Figure 10G (which could also illustrate a PC 1 user exercising an override option to use
15 a level of services above the default standard of one PC microprocessor, presumably at extra cost), for a total of about four, then about 8, about 16, about 32, about 64 and so on, or virtually any number in between, is made available as the network system is upgraded in simple
20 phases over time, as well as the addition of sophisticated override options. As the phase-in process continues, many more PC microprocessors can be made available to the standard PC user (virtually any number), preferably starting at about 128, then about 256, then about 512, then
25 about 1024 and so on over time, as the network and all of its components are gradually upgraded to handle the increasing numbers. System scalability at even the standard user level is essentially unlimited over time.

Preferably, for most standard PC users (including
30 present and future equivalents and successors), connection to the Internet (or present or future equivalents or successors like the MetaInternet) can be at no cost to PC users, since in exchange for such Internet access the PC users can generally make their PC, when idle, available to

the network for shared processing. Preferably, then, competition between Internet Service Providers (including present and future equivalents and successors) for PC user customers can be over such factors as the convenience and
5 quality of the access service provided and of shared processing provided at no addition cost to standard PC users, or on such factors as the level of shared processing in terms, for example of number of slave PC's assigned on a standard basis to a master PC. The ISP's can also compete
10 for parallel processing operations, from inside or outside the ISP Networks, to conduct over their networks..

In addition, as shown in Figures 5A-5B, in another embodiment there is a (hardware and/or software and/or firmware and/or other) controlling device to control access
15 to the user's PC by the network. In its simplest form, such as a manually activated electromechanical switch, the PC user could set this controller device to make the PC available to the network when not in use by the PC user. Alternatively, the PC user could set the controller device
20 to make the PC available to the network whenever in an idle state, however momentary, by making use of multitasking hardware and/or software and/or firmware and/or other component (broadcast or "push" applications from the Internet or other network could still run in the desktop
25 background). Or, more simply, as shown in Figure 5A, whenever the state that all user applications are closed and the PC 1 is available to the network 14 (perhaps after a time delay set by the user, like that conventionally used on screensaver software) is detected by a software
30 controller device 12 installed in the PC, the device 12 signals 15 the network computer such as a server 2 that the PC available to the network, which could then control the PC 1 for parallel processing or multitasking by another PC. Such shared processing can continue until the device 12

detects the an application being opened 16 in the first PC (or at first use of keyboard, for quicker response, in a multitasking environment), when the device 12 signals 17 the network computer such as a server 2 that the PC is no longer available to the network, as shown in Figure 5B, so the network can then terminate its use of the first PC.

In a preferred embodiment, as shown in Figure 6, there is a (hardware and/or software and/or firmware and/or other component) signaling device 18 for the PC 1 to indicate or signal 15 to the network the user PC's availability 14 for network use (and whether full use or multitasking only) as well as its specific (hardware/software/firmware/other components) configuration 20 (from a status 19 provided by the PC) in sufficient detail for the network or network computer such as a server 2 to utilize its capability effectively. In one embodiment, the transponder device is resident in the user PC and broadcast its idle state or other status (upon change or periodically, for example) or respond to a query signal from a network device.

Also, in another embodiment, as shown in Figure 7, there is a (hardware/software and/or firmware and/or other component) transponder device 21 resident in a part of the network (such as network computer, switch, router, or another PC, for examples) that receives 22 the PC device status broadcast and/or queries 26 the PC for its status, as shown in Figure 7.

In one embodiment, as shown in Figure 8, the network also has resident in a part of its hardware and/or software (and/or firmware and/or other components) a capacity such as to allow it to most effectively select and utilize the available user PC's to perform parallel processing initiated by PC users or the network providers or others. To do so, the network should have the (hardware and/or software and/or firmware and/or other component) capability

of locating each PC accurately at the PC's position on the geographic grid lines/connection means 23 so that parallel processing occurs between PC's (PC 1 and PC 1₂) as close together as possible, which should not be difficult for PC's at fixed sites with a geographic location, customarily grouped together into cells 24, as shown in Figure 8, but which requires an active system for any wireless microprocessor to measure its distance from its network relay site, as discussed below in Figure 14.

One of the primary capabilities of the Internet (or Internet II or successor, like the MetaInternet) or WWW network computer is to facilitate searches by the PC user or other user. As shown in Figure 9, searches are particularly suitable to multiple processing, since, for example, a typical search is to find a specific Internet or WWW site with specific information. Such site searches can be broken up geographically, with a different PC processor 1' allocated by the network communicating through a wired means 99 as shown (or wireless connections) to search each area, the overall area being divided into eight separate parts, as shown, which are preferably about equal, so that the total search would be about 1/8 as long as if one processor did it alone (assuming the PC 1 microprocessor provides control only and not parallel processing, which may be preferable in some case).

As a typical example, a single PC user might need 1,000 minutes of search time to find what is requested, whereas the network computer, using multiple PC processors, might be able to complete the search in 100 minutes using 10 processors, or 10 minutes using 100 processors or 1 minute using 1,000 processors (or even 1 second using 60,000 processors); assuming performance transparency, which should be achievable, at least over time. The network's external parallel processing is optimally

completely scalable, with virtually no theoretical limit.

The above examples also illustrates a tremendous potential benefit of network parallel processing. The same amount of network resources, 60,000 processor seconds, was expended in each of the equivalent examples. But by using relatively large multiples of processors, the network can provide the user with relatively immediate response with no difference in cost (or relatively little difference) -- a major benefit. In effect, each PC user linked to the network providing external parallel processing becomes, in effect, a virtual supercomputer! As discussed below, supercomputers can experience a similar quantum leap in performance by employing a thousand-fold (or more) increase in microprocessors above current levels.

15 Such power will likely be required for any effective
searches in the World Wide Web (WWW). WWW is currently
growing at a rate such that it is doubling every year, so
that searching for information within the WWW will become
geometrically more difficult in future years, particularly
20 a decade hence, and it is already a very significant
difficulty to find WWW sites of relevance to any given
search and then to review and analyze the contents of the
site.

So the capability to search with massive parallel
25 processing will be required to be effective and can
dramatically enhance the capabilities of scientific,
technological and medical researchers.

Such enhanced capabilities for searching (and analysis) can also fundamentally alter the relationship of buyers and sellers of any items and/or services. For the buyer, massive parallel network processing can make it possible to find the best price, worldwide, for any product or the most highly rated product or service (for performance, reliability, etc.) within a category or the

best combination of price/performance or the highest rated product for a given price point and so on. The best price for the product can include best price for shipping within specific delivery time parameters acceptable to the buyer.

- 5 For the seller, such parallel processing can drastically enhance the search, worldwide, for customers potentially interested in a given product or service, providing very specific targets for advertisement. Sellers, even producers, can know their customers directly and interact with them directly for feedback on specific products and services to better assess customer satisfaction and survey for new product development.
- 10

- Similarly, the vastly increased capability provided by the system's shared parallel processing can produce major improvements in complex simulations like modeling worldwide and local weather systems over time, as well as design and testing of any structure or product, from airliners and skyscrapers, to new drugs and to the use of much more sophisticated artificial intelligence (AI) in medical treatment and in sorting through and organizing the PC users voluminous input of electronic data from "push" technologies. Improvements in games also result, especially in terms of realistic simulation and realtime interactivity.
- 15
- 20

- 25 As is clear from the examples, the Internet or WWW network computer system like the MetaInternet can potentially put into the hands of the PC user an extraordinary new level of computer power vastly greater than the most powerful supercomputer existing today. The world's total of microchips is already about 350 billion, of which about 15 billion are microprocessors of some kind (most are fairly simple "appliance" type running wrist watches, televisions, cameras, cars, telephones, etc). Assuming growth at its current rates, in a decade the
- 30

Internet/Internet II/WWW could easily have a billion individual PC users, each providing a average total of at least 10 highly sophisticated microprocessors (assuming PC's with at least 4 microprocessors (or more, such as 16 microprocessors or 32, for example) and associated other handheld, home entertainment, and business devices with microprocessors or digital processing capability, like a digital signal processor or successor devices). That results in a global computer a decade from now made of at least 10 billion microprocessors, interconnected by electromagnetic wave means at speeds approaching the speed of light.

In addition, if the exceptionally numerous "appliance" microprocessors noted above, especially those that operate now intermittently like personal computers, are designed to the same basic consensus industry standard as parallel microprocessors for PC's (or equivalents or successors) or for PC "systems on a chip" discussed later in Figure 10A-B, and if also connected by broad bandwidth means such as fiber optic cable or equivalent wireless, then the number of parallel processors potentially available can increase roughly about 10 times, for a net potential "standard" computing performance of up to 10,000 times current performance within fifteen years, exclusive of Moore's Law routine increases. Moreover, in a environment where all currently intermittently operating microprocessors followed the same basic design standards, then although the cost per microprocessor increases somewhat, especially initially, the net cost of computing for all users falls drastically due to the general performance increase due to the use of otherwise idle "appliance" microprocessors. Therefore, the overall system cost reduction compels a transformation of virtually all such microprocessors, which are currently specialty devices known as application-specific integrated

circuits (ASICs), into general microprocessors (like PC's), with software and firmware providing most of their distinguishing functionality.

To put this in context, a typical supercomputer today
5 utilizing the latest PC microprocessors has less than a hundred. Using network linkage to all external parallel processing, a peak maximum of perhaps 1 billion microprocessors can be made available for a network
10 supercomputer user, providing it with the power 10,000,000 times greater than is available using current conventional internal parallel processing supercomputers (assuming the same microprocessor technology). Because of its virtually limitless scalability mentioned above, resources made
15 available by the network to the supercomputer user or PC user can be capable of varying significantly during any computing function, so that peak computing loads can be met with effectively whatever level of resources are necessary.

In summary, regarding monitoring the net provision of power between PC and network, Figures 1-9 show embodiments
20 of a system for a network of computers, including personal computers, comprising: means for network services including browsing functions, as well as shared computer processing such as parallel processing, to be provided to the personal
25 computers within the network; at least two personal computers; means for at least one of the personal computers, when idled by a personal user, to be made available temporarily to provide the shared computer processing services to the network; and means for
30 monitoring on a net basis the provision of the services to each the personal computer or to the personal computer user. In addition, Figures 1-9 show embodiments including where the system is scalar in that the system imposes no limit to the number of the personal computers, including at least 1024 personal computers; the system is scalar in that

the system imposes no limit to the number of personal computers participating in a single shared computer processing operation, including at least 256 personal computers; the network is connected to the Internet and its equivalents and successors, so that the personal computers include at least a million personal computers; the network is connected to the World Wide Web and its successors; the network includes at least one network server that participates in the shared computer processing.; the monitoring means includes a meter device to measure the flow of computing power between the personal computers and the network; the monitoring means includes a means by which the personal user of the personal computer is provided with a prospective estimate of cost for the network to execute an operation requested by the personal user prior to execution of the operation by the network; the system has a control means by which to permit and to deny access to the personal computers by the network for shared computer processing; access to the personal computers by the network is limited to those times when the personal computers are idle; and the personal computers having at least one microprocessor and communicating with the network through a connection means having a speed of data transmission that is at least greater than a peak data processing speed of the microprocessor.

Also, relative to maintaining a standard cost, Figures 1-9 show embodiments of a system for a network of computers, including personal computers, comprising: means for network services including browsing functions, as well as shared computer processing such as parallel processing, to be provided to the personal computers within the network; at least two personal computers; means for at least one of the personal computers, when idled by a personal user, to be made available temporarily to provide

the shared computer processing services to the network; and means for maintaining a standard cost basis for the provision of the services to each personal computer or to the personal computer user. In addition, Figures 1-9 show

5 embodiments including where the system is scalar in that the system imposes no limit to the number of personal computers, including at least 1,024 personal computers; the system is scalar in that the system imposes no limit to the number of the personal computers participating in a single

10 shared computer processing operation, including at least 256 personal computers; the network is connected to the Internet and its equivalents and successors, so that the personal computers include at least a million personal computers; the standard cost is fixed; the fixed standard

15 cost is zero; the means for maintaining a standard cost basis includes the use of making available a standard number of personal computers for shared processing by personal computers; the network is connected to the World Wide Web and its successors; the personal user can override

20 the means for maintaining a standard cost basis so that the personal user can obtain additional network services; the system has a control means by which to permit and to deny access to the personal computers by the network for shared computer processing; the personal computers having at least

25 one microprocessor and communicating with the network through a connection means having a speed of data transmission that is at least greater than a peak data processing speed of the microprocessor.

Browsing functions generally include functions like

30 those standard functions provided by current Internet browsers, such as Microsoft Explorer 3.0 or 4.0 and Netscape Navigator 3.0 or 4.0, including at least access to searching World Wide Web or Internet sites, exchanging E-Mail worldwide, and worldwide conferencing; an intranet

network uses the same browser software, but might not include access to the Internet or WWW. Shared processing includes parallel processing and multitasking processing involving more than two personal computers, as defined above. The network system is entirely scalar, with any number of PC microprocessors potentially possible.

As shown in Figures 10A-10F, to deal with operational and security issues, it may be optimal for individual users to have one microprocessor or equivalent device that is designated, permanently or temporarily, to be a master controlling device (comprised of hardware and/or software and/of firmware and/or other component) that remains inaccessible (preferably using a hardware and/or software and/or firmware and/or other component firewall) directly by the network but which controls the functions of the other, slave microprocessors when the network is not utilizing them.

For example, as shown in Figures 10A, a typical PC might have four or five microprocessors (even on a single microprocessor chip), with one master and three or four slaves, depending on whether the master is a controller exclusively (through different design of any component part), requiring four slave microprocessors preferably; or the master microprocessor has the same or equivalent microprocessing capability as a slave and multiprocesses in parallel with the slave microprocessors, thereby requiring only three slave microprocessors preferably. The number of PC slave microprocessors can be increased to virtually any other number, such as at least about eight, about 16, about 32, about 64, about 128, about 256, about 512, about 1024, and so on (these multiples are preferred as conventional in the art, but not clearly required; the PC master microprocessors can also be increased. Also included is the preferred firewall

50 between master 30 and slave 40 microprocessors. As shown in preceding Figures 1-9, the PC 1 in Figure 10A is preferably connected to a network computer 2 and to the Internet or WWW or present or future equivalent or successor 3, like the MetaInternet.

Other typical PC hardware components such as hard drive 61, floppy diskette 62, CD-ROM 63, DVD 64, Flash memory 65, RAM 66, video or other display 67, graphics card 68, and sound card 69, together with the software and/or firmware stored on or for them, can be located on either side of the preferred firewall 50, but such devices as the display 67, graphics card 68 and sound card 69 and those devices that both read and write and have non-volatile memory (retain data without power and generally have to be written over to erase), such as hard drive 62, Flash memory 65, floppy drive 62, read/write CD-ROM 63 or DVD 64 are preferred to be located on the PC user side of the firewall 50, where the master microprocessor is also located, as shown in Figure 10A, for security reasons primarily.

Alternately, any of these devices that are duplicative (or for other exceptional needs), like a second hard drive 61', can be located on the network side of the firewall 50.

RAM 66 or equivalent memory, which typically is volatile (data is lost when power is interrupted), should generally be located on the network side of the firewall 50. However, read-only memory devices such as most current CD drives (CD-ROM's) 63' or DVD's (DVD-ROM) 64' can be safely located on the network side of the firewall 50, since the data on those drives cannot be altered by network users; preemptive control of use preferably remains with the PC user.

However, at least a portion of RAM is can be kept on the Master 30 microprocessor side of the firewall 50, so that the PC user can use retain the ability to use a core

of user PC 1 processing capability entirely separate from any network processing. If this capability is not desired, then the master 30 microprocessor can be moved to the network side of the firewall 50 and replaced with a simpler
5 controller on the PC 1 user side, like the master remote controller 31 discussed below and shown in Figure 10I.

And the master microprocessor 30 might also control the use of several or all other processors 60 owned or leased by the PC user, such as home entertainment digital
10 signal processors 70, especially if the design standards of such microprocessors in the future conforms to the requirements of network parallel processing as described above. In this general approach, the PC master processor uses the slave microprocessors or, if idle (or working on
15 low priority, deferrable processing), make them available to the network provider or others to use. Preferably, wireless connections 100 are extensively used in home or business network systems, including use of a master remote controller 31 without (or with) microprocessing capability,
20 with preferably broad bandwidth connections such as fiber optic cable connecting directly to at least one component such as a PC 1, shown in a slave configuration, of the home or business personal network system; that preferred connection links the home system to the network 2 such as
25 the Internet 3, as shown in Figure 10I.

In the simplest configuration, as shown in Figure 10B, the PC 1 has a single master microprocessor 30 and a single slave microprocessor 40, preferably separated by a firewall 50, with both processors used in parallel or multitasking
30 processing or with only the slave 40 so used, and preferably connected to a network computer 2 and Internet 3 (and successors like the MetaInternet). Virtually any number of slave microprocessors 40 is possible. The other non-microprocessor components shown in Figure 10A above

might also be included in this simple Figure 10B configuration.

Preferably, as shown in Figure 10C, microprocessors 90 are expected to integrate most or all of the other necessary computer components (or their present or future equivalents or successors), like a PC's memory (RAM 66, graphics 82, sound 83, power management 84, network communications 85, and video processing 86, possibly including modem 87, flash bios 88, and other components or present or future equivalents or successors) and internal bus, on a single chip 90 (silicon, plastic, or other), known in the industry as "system on a chip". Such a PC micro chip 90 preferably has the same architecture as that of the PC 1 shown above in Figure 10A: namely, a master control and/or processing unit 93 and one or more slave processing units 94 (for parallel or multitasking processing by either the PC 1 or the Network 2), preferably separated by a firewall 50 and preferably connected to a network computer 3 and the Internet 3 and successors like the MetaInternet.

Existing PC components with mechanical components like hard drive 61, floppy or other removable diskette 62, CD-ROM 63 and DVD 64, which are mass storage devices that will likely not become an integral part of a PC "system of a chip" preferably, of course, still is capable of connection to a single PC micro chip 90 and control by a single PC master unit 93.

In the simplest case, as shown in Figure 10D, the chip 90 has a single master unit 93 and at least one slave unit 94 (with the master having a controlling function only or a processing function also), preferably separated by a firewall 50 and preferably connected to a network computer 3 and the Internet 3 (and successors like the MetaInternet).

As noted in the second paragraph of the introduction to the background of the invention, in the preferred network invention, any computer can potentially be both a user and provider, alternatively -- a dual mode.

- 5 Consequently, any PC 1 within the network 2, preferably connected to the Internet 3 (and successors like the MetaInternet), can be temporarily a master PC 30 at one time initiating a parallel or multitasking processing request to the network 2 for execution by at least one
- 10 slave PC 40, as shown in Figure 10E. At another time the same PC 1 can become a slave PC 40 that executes a parallel or multitasking processing request by another PC 1' that has temporarily assumed the function of master 30, as shown in Figure 10F. The simplest approach to achieving this
- 15 alternation is for both master and slave versions of the parallel processing software to be loaded in each or every PC 1 that is to share in the parallel processing, so each PC 1 has the necessary software means, together with minor operation modifications, such as a switching means by which
- 20 a signal request for parallel processing initiated by one PC 1 user using master software is transmitted to at least a second PC 1, triggering its slave software to respond to initiate parallel processing.

- As shown in Figures 10G and 10H, which are parallel to
- 25 Figures 10E and 10F, the number of PC slave processors 40 can be increased to any virtually other number, such as at least about 4; the processing system is completely scalar, so that further increases can occur to about eight, about 16, about 32, about 64, about 128, about 256, about 512,
- 30 about 1024, and so on (these multiples indicated are preferred as conventional in the art, but not mandatory); the PC master microprocessors 30 can also be increased.

In summary, as noted above relative to Figure 10I, a PC 1 can function as a slave PC 40 and be controlled by a

master controller 31, which can be remote and which preferably can have limited or no microprocessing capability, but can as well have similar or greater capability. As shown in Figures 10J and 10K, such a master controller 31 is located on the PC user side of the firewall 50, under the control of the PC user, while the microprocessors 40 reside on the network side of the firewall 50. The master controller 31 preferably receives input from the PC user by local means such as keyboard, microphone, videocam or future hardware and/or software and/or firmware or other equivalent or successor means (as does a master processor 40); in addition, remote access by telephone, cable, wireless or other connection might also be enabled by a hardware and/or software and/or firmware and/or other means with suitable security such as password controlled access. Similarly, as shown in Figures 10L and 10M, relative to a PC "system on a chip" a master controller unit 93' (which could be capable of being accessed by the PC user through a remote controller 31) with only a controlling capability is located on the PC user side of the firewall 50, under the control of the PC user (and potentially including control by a network systems administrator), while the slave processor units 94 reside on the network side of the firewall 50.

Figures 10N and 10O show PC 1 with a firewall 50 that is configurable through either hardware and/or software and/or firmware and/or other means; software configuration are easiest and most typical, but active motherboard hardware configuration is possible and may present some security advantages, including as use of manual or electromechanical or other switches or locks. Figure 10N shows a CD-ROM 63' that has been placed by a PC user on the network side of a firewall 50 from a previous position on the PC user side of a firewall 50, which was shown in

Figure 10A. Preferably, the settings of a firewall 50 can default to those that safely protect the PC 1 from uncontrolled access by network users, but with capability for the relatively sophisticated PC user to override such default settings and yet with proper safeguards to protect the unsophisticated user from inadvertently doing so; configuration of a firewall 50 might also be actively controlled by a network administrator in a local network like that of a business, where a PC user may not be owner or leaser of the PC being used, either by remote access on the network or with a remote controller 31.

Similarly, Figures 10P and 10Q show a PC "system of a chip" 90 with a firewall 50 that is configurable through either hardware and/or software and/or firmware and/or other means; software configuration is easiest and most typical. Active configuration of the integrated circuits of the PC microchip 90 is also possible and may present some speed and security advantages. Such direct configuration of the circuits of the microchip 90 to establish or change in its firewall 50 could be provided by the use of field-programmable gate arrays (or FPGA's) or their future equivalents or successors; microcircuit electromechanical or other switches or locks can also be used potentially. In Figure 10P, for example, slave processing unit 94' has been moved to the PC user side of a firewall 50 from a network side position shown in Figure 10C and 10L. Similarly, Figure 10Q shows the same active configuration of chip circuit using FPGA's for the simplest form of multiprocessing microchip 90 with a single slave unit 94', transferring its position to the PC user's side of a firewall 50 from a network side shown in Figure 10M and 10D.

In summary, relative to the use of master/slave computers, Figures 10A-10I show embodiments of a system for

a network of computers, including personal computers, comprising: at least two personal computers; means for at least one personal computer, when directed by its personal user, to function temporarily as a master personal computer to initiate and control the execution of a computer processing operation shared with at least one other the personal computer in the network; means for at least one other personal computer, when idled by its personal user, to be made available to function temporarily as at least one slave personal computer to participate in the execution of a shared computer processing operation controlled by the master personal computer; and means for the personal computers to alternate as directed between functioning as a master and functioning as a slave in the shared computer processing operations. In addition, Figures 10A-10H show embodiments including wherein the system is scalar in that the system imposes no limit to the number of personal computers; for example, the system can include at least 256 said personal computers; the system is scalar in that the system imposes no limit to the number of personal computers participating in a single shared computer processing operation, including at least 256 said personal computers, for example; the network is connected to the Internet and its equivalents and successors, so that personal computers include at least a million personal computers, for example; the shared computer processing is parallel processing; the network is connected to the World Wide Web and its successors; a means for network services, including browsing and broadcast functions, as well as shared computer processing such as parallel processing, are provided to said personal computers within said network; the network includes at least one network server that participates in the shared computer processing; the personal computers include a transponder or equivalent or

successor means so that a master personal computer can determine the closest available slave personal computers; the closest available slave personal computer is compatible with the master personal computer to execute said shared computer processing operation; the personal computers having at least one microprocessor and communicating with the network through a connection means preferably having a speed of data transmission that is at least greater than a peak data processing speed of the microprocessor.

- 10 The preferred use of the firewall 50, as described above in Figures 10A-10I, provides a solution to an important security problem by preferably completely isolating host PC's 1 that are providing slave microprocessors to the network for parallel or other shared processing functions from any capability to access or
- 15 retain information about any element about that shared processing. In addition, of course, the firewall 50 provides security for the host PC against intrusion by outside hackers; by reducing the need for encryption and authentication, the use of firewalls 50 can provide a
- 20 relative increase in computing speed and efficiency. In addition to computers such as personal computers, the firewall 50 described above could be used in any computing device included in this application's above definition of
- 25 personal computers, including those with "appliance"-type microprocessors, such as telephones, televisions or cars, as discussed above.

- In summary, regarding the use of firewalls, Figures 10A-10H show embodiments of a system architecture for
- 30 computers, including personal computers, to function within a network of computers, comprising: a computer with at least two microprocessors and having a connection means with a network of computers; the architecture for the computers including a firewall means for personal computers

to limit access by the network to only a portion of the hardware, software, firmware, and other components of the personal computers; the firewall means does not permit access by the network to at least one microprocessor having
5 a means to function as a master microprocessor to initiate and control the execution of a computer processing operation shared with at least one other microprocessor having a means to function as a slave microprocessor; and the firewall means permitting access by the network to the
10 slave microprocessor. In addition, the system architecture explicitly includes embodiments of, for example, the computer is a personal computer; the personal computer is a microchip; the computer has a control means by which to permit and to deny access to the computer by the network
15 for shared computer processing; the system is scalar in that the system imposes no limit to the number of personal computers, including at least 256 said personal computers; the network is connected to the Internet and its equivalents and successors, so that the personal computers
20 include at least a million personal computers; the system is scalar in that the system imposes no limit to the number of personal computers participating in a single shared computer processing operation, including at least 256 said personal computers; the personal computers having at least
25 one microprocessor and communicating with the network through a connection means having a speed of data transmission that is preferably at least greater than a peak data processing speed of the microprocessor.

In summary, regarding the use of controllers with
30 firewalls, Figures 10J-10M show embodiments of a system architecture for computers, including personal computers, to function within a network of computers, comprising for example: a computer with at least a controller and a microprocessor and having a connection means with a network

of computers; the architecture for the computers including a firewall for personal computers to limit access by the network to only a portion of the hardware, software, firmware, and other components of the personal computers; the firewall does not permit access by the network to at least a one controller having a means to initiate and control the execution of a computer processing operation shared with at least one microprocessor having a means to function as a slave microprocessor; and the firewall permitting access by the network to the slave microprocessor. In addition, the system architecture explicitly includes embodiments of, for example, the computer is a personal computer; the personal computer is a microchip; the computer have a control means by which to permit and to deny access to the computer by the network for shared computer processing; the system is scalar in that the system imposes no limit to the number of personal computers, including at least 256 said personal computers; the network is connected to the Internet and its equivalents and successors, so that the personal computers include at least a million personal computers; the system is scalar in that the system imposes no limit to the number of personal computers participating in a single shared computer processing operation, including at least 256 said personal computers; the personal computers having at least one microprocessor and communicating with the network through a connection means having a speed of data transmission that is preferably at least greater than a peak data processing speed of the microprocessor; and the controller being capable of remote use.

In summary, regarding the use of firewalls that can be actively configured, Figures 10N-10Q show embodiments of a system architecture for computers, including personal computers, to function within a network of computers,

comprising for example: a computer with at least two microprocessors and having a connection with a network of computers; the architecture for the computers including a firewall means for personal computers to limit access by
5 the network to only a portion of the hardware, software, firmware, and other components of the personal computers; the firewall does not permit access by the network to at least a one microprocessor having a means to function as a master microprocessor to initiate and control the execution
10 of a computer processing operation shared with at least one other microprocessor having a means to function as a slave microprocessor; the firewall permitting access by the network to the slave microprocessor; the configuration of the firewall being capable of change by a user or
15 authorized local network administrator; the change in firewall configuration of a microchip PC is made at least in part using field-programmable gate arrays or equivalents or successors. In addition, the system architecture explicitly includes embodiments of, for example, the
20 computer is a personal computer; the personal computer is a microchip; the computer have a control means by which to permit and to deny access to the computer by the network for shared computer processing; the system is scalar in that the system imposes no limit to the number of personal
25 computers; including at least 256 said personal computers; the network is connected to the Internet and its equivalents and successors, so that the personal computers include at least a million personal computers; the system is scalar in that the system imposes no limit to the number
30 of personal computers participating in a single shared computer processing operation, including at least 256 said personal computers; the personal computers having at least one microprocessor and communicating with the network through a connection means having a speed of data

transmission that is preferably at least greater than a peak data processing speed of the microprocessor.

If the PC 1 microprocessors noted above are designed to the same basic consensus industry standard as parallel
5 microprocessors for PC's (or equivalents or successors) as in Figures 10A-10B or for PC "systems on a chip" discussed in Figures 10C-10D, then although the cost per microprocessor can rise somewhat, especially initially, the net cost of computing for all users falls drastically
10 almost instantly due to the general performance increase due to the use of otherwise idle "appliance" microprocessors. The potential very substantial benefit to all users should provide a powerful force to reach consensus on important industry hardware, software, and
15 other standards on a continuing basis for such basic parallel network processing designs. If such basic industry standards are adopted at the outset and for the least number of shared microprocessors initially, and if design improvements incorporating greater complexity and
20 more shared microprocessors are phased in gradually overtime on a step by step basis, then conversion to a MetaInternet architecture at all component levels should be relatively easy and inexpensive (whereas an attempt at sudden, massive conversion is hugely difficult and
25 prohibitively expensive). The scalability of the MetaInternet system architecture (both vertically and horizontally) as described herein makes this sensible approach possible.

By 1998, manufacturing technology improvements allow
30 20 million transistors to fit on a single chip (with circuits as thin as .25 microns) and, in the next cycle, 50 million transistors using .18 micron circuits. Preferably, that entire computer on a chip is linked, preferably directly, by fiber optic or other broad bandwidth

connection means so that the limiting factor on data throughput in the network system, or any part, is the speed of the linked microprocessors themselves.

For computers that are not reduced to a single chip, it is also preferred, but not mandatory for a substantial useful benefit, that the internal bus of any such PC's have a transmission speed that is at least high enough that the all processing operations of the PC microprocessor or microprocessors is unrestricted and that the microprocessor chip or chips are directly linked by fiber optic or other broad bandwidth connection, as with the system chip described above.

The individual user PC's can be connected to the Internet (via an Intranet)/Internet II/WWW or successor, like the MetaInternet (or other) network by any electromagnetic means, with the broadbandwidth speed of fiber optic cable being preferred, but hybrid systems using fiber optic cable for trunk lines and coaxial cable to individual users may be more cost effective initially, but less preferred unless cable can be made (through hardware and/or software and/or firmware and/or other component means) to provide sufficiently broad bandwidth connections to provide unrestricted throughput by connected microprocessors. Given the speed and bandwidth of transmission of fiber optic or equivalent connections, conventional network architecture and structures should be acceptable for good system performance, making possible a virtual complete interconnection network between users.

However, the best speed for any parallel processing operation should be obtained, all other things being equal, by utilizing the available microprocessors that are physically the closest together. Consequently, as shown previously in Figure 8, the network needs have the means (through hardware and/or software and/or firmware and/or

other component) to provide on a continually ongoing basis the capability for each PC to know the addresses of the nearest available PC's, perhaps sequentially, from closest to farthest, for the area or cell immediately proximate to that PC and then those cells of adjacent areas.

Network architecture that clusters PC's together should therefore be preferred, but not mandatory for substantial benefit, and can be constructed by wired means.

However, as shown in Figure 11, it is probably optimal to construct local network clusters 101 (or cells) of personal computers 1' by wireless 100 means, since physical proximity of any PC 1 to its closest other PC 1' should be easier to access directly that way, as discussed further below. Besides, it is economically preferable for at least several network providers to serve any given geographic area to provide competitive service and prices.

Optimally, then, those wireless PC connections should be PC resident and capable of communicating by wireless or wired means with all available PC's in the cluster or cell geographic area, both proximal and potentially out to the practical limits of the wireless transmission.

As shown in Figure 12, wireless PC connections 100 can be made to existing non-PC network components, such as one or more satellites 110, or present or future equivalent or successor components and the wireless transmissions can be conventional radio waves, such as infrared or microwave, or any other part of the electromagnetic wave spectrum.

Moreover, as shown in Figure 13, such a wireless or wired approach also make it easily possible in the future to develop network clusters 101 of available PC's 1' with complete interconnectivity; i.e., each available PC 1 in the cluster 101 is directly connected (preferably wirelessly 100) to every other available PC 1 in the cluster 101, constantly adjusting to individual PC's

becoming available or unavailable. Given the speed of some wired broad bandwidth connections, like fiber optic cable, such clusters 101 with complete interconnectivity is certainly a possible embodiment.

- 5 As shown in Figure 14A-14D, such wireless systems optimally include a wireless device 120 comprised of hardware and/or software and/or firmware and/or other component, like the PC 1 availability device described above preferably resident in the PC, but also with a
- 10 network-like capability of measuring the distance from each PC 1 in its cluster 101 by that PC's signal transmission by transponder or its functional equivalent and/or other means to the nearest other PC's 1' in the cluster 101. As shown in Figure 14A, this distance measurement could be
- 15 accomplished in a conventional manner between transponder devices 120 connected to each PC in the cluster 101; for example, by measuring in effect the time delay from wireless transmission by the transponder device 120 of an interrogating signal 105 to request initiation of shared
- 20 processing by a master PC 1 to the reception of a wireless transmission response 106 signaling availability to function as a slave PC from each of the idle PC's 1' in the cluster 101 that has received the interrogation signal 105.

- The first response signal 106' received by the master PC 1
- 25 is from the closest available slave PC 1' (assuming the simplest shared processing case of one slave PC and one master PC), which is selected for the shared processing operation by the requesting master PC 1, since the closer the shared microprocessor, the faster the speed of the
- 30 wireless connections 100 is between sharing PC's (assuming equivalence of the connection means and other components among each of the PC's 1'). The interrogation signal 105 might specify other selection criteria also, for example, for the closest compatible (initially perhaps defined by a

functional requirement of the system to be an identical microprocessor) slave PC 1", with the first response signal 106' being selected as above.

This same transponder approach also can be used
5 between PC's 1" connected by a wired 99 means, despite the fact that connection distances is generally greater (since not line of sight, as is wireless), as shown in Figure 14A, since the speed of transmission by the preferred broad bandwidth transmission means such as fiber optic cable is
10 so high as to offset that greater distance. From a cost basis, this wired approach might be preferable for such PC's already connected by broad bandwidth transmission means, since additional wireless components like hardware and software are not necessary. In that case, the same
15 transponder device 120 preferably is operated in wired clusters 101 in generally the same manner as described above for PC's connected in wireless clusters 101. Networks incorporating PC's 1 connected by both wireless and wired means are anticipated, like the home or business
20 network mentioned in Figure 10I, with mobile PC's or other computing devices preferably using wireless connections. Depending on distances between PC's and other factors, a local cluster 101 of a network 2 might connect wirelessly between PC's and with the network 2 through transponding
25 means linked to wired broad bandwidth transmission means, as shown in Figure 14C.

As shown in Figure 14D, the same general transponder device means 120 can also be used in a wired 100 network system 2 employing network servers 98 operated, for
30 example, by an ISP, or in other network system architectures (including client/server or peer to peer) or topologies (including ring, bus, and star) well known in the art or their future equivalents or successors.

The Figure 14 approach to establishing local PC

clusters 101 for parallel or other shared processing has major advantage in that it avoids using network computers such as servers (and, if wireless, other network components including even connection means), so that the entire local system of PC's within a cluster 101 operates independently of network servers, routers, etc. Moreover, particularly if connected by wireless means, the size of the cluster 101 could be quite large, being limited generally by PC transmission power, PC reception sensitivity, and local conditions. Additionally, one cluster 101 could communicate by wireless means with an adjacent or other clusters 101, as shown in Figure 14B, which could include those beyond its direct transmission range.

To improve response speed in shared processing involving a significant number of slave PC's 1, a virtual potential parallel processing network for PC's 1 in a cluster 101 preferably is established before a processing request begins. This is accomplished by the transponder device 120 in each idle PC 1, a potential slave, broadcasting by transponder 120 its available state when it becomes idle and/or periodically afterwards, so that each potential master PC 1 in the local cluster 101 is able to maintain relatively constantly its own directory 121 of the idle PC's 1 closest to it that are available to function as slaves. The directory 121 contains, for example, a list of about the standard use number of slave PC's 1 for the master PC (which initially probably is just one other PC 1") or a higher number, preferably listed sequentially from the closest available PC to the farthest. The directory of available slave PC's 1 is preferably updated on a relatively up to date basis, either when a change occurs in the idle state of a potential slave PC in the directory 121 or periodically.

Such ad hoc clusters 101 should be more effective by

being less arbitrary geographically, since each individual PC is effectively in the center of its own ad hoc cluster.

Scaling up or down the number of microprocessors required by each PC at any given time is also more seamless.

- 5 The complete interconnection potentially provided optimally by such ad hoc wireless clusters is also remarkable because such clusters mimics the neural network structure of the animal brain, wherein each nerve cell, called a neuron, interconnects in a very complicated way
10 with the neurons around it. By way of comparison, the global network computer described above that is expected in a decade can have at least about 10 times as many PC 's as a human brain has neurons and they can be connected by electromagnetic waves traveling at close to the speed of
15 light, which is about 300,000 times faster than the transmission speed of human neurons (which, however, are much closer together).

- An added note: in the next decade, as individual PC's become much more sophisticated and more network oriented,
20 compatibility issues may recede to unimportance, since all major types of PC's will be able to emulate each other and most software, particularly relative to parallel processing, will no longer be hardware specific. Nearer term it will be important to set compatible hardware,
25 software, firmware, and other component standards to achieve optimal performance by the components of the global network computer.

- Until that compatibility is designed into the essential components of network system, the existing
30 incompatibility of current components dramatically increase the difficulty involved in parallel processing across large networks. Programming languages like Java is one approach that will provide a partial means for dealing with this interim problem. In addition, using similar configurations

of existing standards, like using PC's with a specific Intel Pentium chip with other identical or nearly identical components is probably the best way in the current technology to eliminate many of the serious existing problems that could easily be designed around in the future by adopting reasonable consensus standards for system components. The potential gains to all parties with an interest far outweigh the potential costs.

The above described global network computer system has an added benefit of reducing the serious and growing problem of nearly the immediate obsolescence of computer hardware, software, firmware, and other components. Since the preferred system above is the sum of its constituent parts used in parallel processing, each specific PC component becomes less critical. As long as access to the network utilizing sufficient bandwidth is possible, then all other technical inadequacies of the user's own PC can be completely compensated for by the network's access to a multitude of technically able PC's of which the user will have temporary use.

Although the global network computer will clearly cross the geographical boundaries of nations, its operation should not be unduly bounded by inconsistent or arbitrary laws within those states. There will be considerable pressure on all nations to conform to reasonable system architecture and operational standards generally agreed upon, since the penalty of not participating in the global network computer is potentially so high as to not be politically possible anywhere.

As shown in Figure 15, because the largest number of user PC's are completely idle, or nearly so, during the night, it can be useful for the most complicated large scale parallel processing, involving the largest numbers of processors with uninterrupted availability as close

together as possible, to be routed by the network to geographic areas of the globe undergoing night and to keep them there even as the Earth rotates by shifting computing resources as the world turns. As shown in Figure 15, during the day, at least one parallel processing request by at least one PC 1 in a network 2 in the Earth's western hemisphere 131 are transmitted by very broad bandwidth connection wired 99 means such as fiber optic cable to the Earth's eastern hemisphere 132 for execution by at least one PC 1' of a network 2', which is idle during the night and the results are transmitted back by the same means to network 2 and the requesting at least one PC 1. Individual PC's within local networks like that operated by an ISP can be grouped into clusters or cells, as is typical in the practice of network industries. As is common in operating electrical power grids and telecommunications and computer networks, many such processing requests from many PC's and many networks could be so routed for remote processing, with the complexity of the system growing substantially over time in a natural progression.

This application encompasses all new apparatus and methods required to operate the above described network computer system or systems, including any associated computer or network hardware, software, or firmware (or other component), both apparatus and methods. Specifically included, but not limited to, are (in their present or future forms, equivalents, or successors): all enabling PC and network software and firmware operating systems, user interfaces and application programs; all enabling PC and network hardware design and system architecture, including all PC and other computers, network computers such as servers, microprocessors, nodes, gateways, bridges, routers, switches, and all other components; all enabling financial and legal transactions, arrangements and entities

for network providers, PC users, and/or others, including purchase and sale of any items or services on the network or any other interactions or transactions between any such buyers and sellers; and all services by third parties, including to select, procure, set up, implement, integrate, operate and perform maintenance, for any or all parts of the foregoing for PC users, network providers, and/or others.

The combinations of the many elements the applicant's invention introduced in the preceding figures are shown because those embodiments are considered to be at least among the most useful possible, but many other useful combination embodiments are not shown simply because of the impossibility of showing them all, while at the same time maintaining a reasonable brevity in an unavoidably long description caused by the inherently highly connected nature of the inventions shown herein, which generally can operate all as part of one system of independently.

Therefore, any combination that is not explicitly described above is definitely implicit in the overall invention of this application and, consequently, any part of any of the preceding Figures and/or associated textual description can be combined with any part of any one or more other of the Figures and/or associated textual description of this application to create new and useful improvements over the existing art.

In addition, any unique new part of any of the preceding Figures and/or associated textual description can be considered by itself alone as an individual improvement over the existing art.

The foregoing embodiments meet the overall objectives of this invention as summarized above. However, it will be clearly understood by those skilled in the art that the foregoing description has been made in terms only of the

most preferred specific embodiments. Therefore, many other changes and modifications clearly and easily can be made that are also useful improvements and definitely outside the existing art without departing from the scope of the present invention, indeed which remain within its very broad overall scope, and which invention is to be defined over the existing art by the appended claims.

I CLAIM AS MY INVENTION:

1. A system architecture for computers, including personal computers, to function within a network of computers, comprising:

a computer with at least one controller and at least one microprocessor, said computer including a connection with a network of computers;

said architecture for said computers including a firewall for personal computers to limit access by said network to only a portion of hardware, software, firmware, and other components of said personal computers;

said firewall will not permit access by said network to said at least one controller including means for functioning as a master to initiate and control execution of a computer processing operation shared with said at least one other microprocessor including means for functioning as a slave microprocessor; and

said firewall permitting access by said network to said slave microprocessor.

2. The system architecture of claim 1, wherein said computer is a personal computer.

3. The system architecture of claim 2, wherein said personal computer is a microchip.

4. The system architecture of claim 1, wherein said computer includes means for permitting and for denying access to said computer by said network for shared computer processing.

5. The system architecture of claim 2, wherein said system includes at least 256 of said personal computers.

6. The system architecture of claim 2, wherein said network is connected to an Internet, so that said personal computers include at least one million personal computers.

7. The system architecture of claim 2, wherein said system includes at least 256 of said personal computers capable of participating in a single shared computer processing operation.

8. The system architecture of claim 2, wherein said personal computers include at least one microprocessor and said personal computers are arranged to communicate with said network through a connection having a speed of data transmission that is at least greater than a peak data processing speed of said at least one microprocessor.

9. The system architecture of claim 2, wherein said at least one controller is capable of being used remotely from another one of said personal computers.

10. A system architecture for computers, including personal computers, to function within a network of computers, comprising:

a computer with at least two microprocessors and having a connection with a network of computers;

said architecture for said computers including a firewall by which said personal computers limit access by said network to only a portion of hardware, software, firmware, and other components of said personal computers;

said firewall not permitting access by said network to at least one of said at least two microprocessors, said at least one of said at least two microprocessors including means for functioning as a master microprocessor and for initiating and controlling execution of a computer processing operation shared with at least one other microprocessor including means for functioning as a slave microprocessor;

said firewall permitting access by said network to said slave microprocessor; and

a configuration of said firewall capable of being changed by a computer user or an authorized local network administrator.

11. The system architecture of claim 10, wherein said computer is a personal computer.

12. The system architecture of claim 10, wherein said personal computer is a microchip.

13. The system architecture of claim 10, wherein said computer include means for permitting and for denying access to said computer by said network for shared computer processing.

14. The system architecture of claim 11, wherein said system includes at least 256 of said personal computers.

15. The system architecture of claim 11, wherein said network is connected to an Internet, so that said personal computers include at least one million personal computers.

16. The system architecture of claim 11, wherein at least 256 of said personal computers participate in a single shared computer processing operation.

17. The system architecture of claim 11, wherein said personal computers include at least one microprocessor and are arranged to communicate with said network through a connection having a speed of data transmission that is at least greater than a peak data processing speed of said at least one microprocessor.

18. The system architecture of claim 11, wherein said change in a firewall configuration is made, at least in part, by using field-programmable gate arrays.
